Abstract—We propose a new method for imputation of missing values in large scale matrix data based on a low-rank tensor approximation technique called the block tensor train (TT) decomposition. Given sparsely observed data points, the proposed method iteratively computes the soft-thresholded singular value decomposition (SVD) of the underlying data matrix with missing values. The SVD of matrices is performed based on a low-rank block TT decomposition for large scale data matrices with a low-rank tensor structure. Experimental results on simulated data demonstrate that the proposed method can estimate a large amount of missing values accurately compared to a matrix-based standard method.

I. INTRODUCTION

In this paper, we propose a new method for estimating missing values in large scale matrix data

\[ Y \in \mathbb{R}^{I \times J_1 \times J_2 \cdots J_N}, \]  

by extending standard iterative soft-thresholded singular value decomposition (SVD) to block tensor train (TT) decomposition as an efficient low-rank data structure. The SVD is a mathematical technique which factorizes a matrix into the product of matrices of left singular vectors, right singular vectors, and singular values. In statistics and data mining, the SVD has been used as a key numerical technique for multivariate data analyses such as principal component analysis (PCA) and multiple regression analysis. The SVD has a wide range of applications in areas such as ecology [4] and recommender systems [7], [10].

A tensor refers to a multi-dimensional array, which can be considered as a generalization of vectors and matrices. Tensor decomposition, like matrix SVD, has been developed for a wide scope of applications in signal processing, machine learning, chemometrics, and neuroscience [9]. Traditional tensor decompositions include Candecomp/Parafac (CP) decomposition and Tucker decomposition; see, e.g., [9]. Modern tensor decompositions have been developed more recently to cope with the problem called as the curse-of-dimensionality, which means an exponential rate of increase in the storage and computational costs as the dimensionality of tensors increases [5], [8].

The tensor train (TT) decomposition is one of the modern tensor decompositions which generalize the matrix SVD to higher-order (i.e., multi-dimensional) tensors [16]. Modern tensor decompositions such as the TT decomposition applies not only to higher order tensors, but also to large scale vectors and matrices, by transforming the vectors and matrices into higher-order tensors via a tensorization process [2]. Once the large scale vectors and matrices have been decomposed by TT decomposition, algebraic operations such as the matrix-by-vector multiplication can be performed much efficiently with logarithmically scaled computational costs [16].

In this work, we focus on the so-called block TT decomposition, which is one of the TT representations of large scale matrices. The block TT decomposition has been used for approximately computing a set of eigenvectors or singular vectors of large scale matrices [3], [11], [12], [13]. Compared to the other TT representations for matrices, the block TT decomposition is suitable for approximating low-rank data matrices, which is a typical assumption of standard imputation methods based on matrix SVD.

For SVD of large data matrices with missing values, [15] proposed an iterative soft-thresholding algorithm. In that algorithm, a convex optimization problem is suggested and solved by an iterative process consisting of soft-thresholding SVD and missing data imputation. The SVD plays a crucial role for estimating missing values of large matrices based on its low-rank constraints and soft-thresholding regularization. We remark that other SVD-based missing data imputation algorithms have been developed in recent decades, see, e.g., references in [4], [15].

In this study, we propose an iterative soft-thresholding algorithm based on the block TT decomposition. In the proposed algorithm, the missing values in large scale matrix data are estimated based on soft-thresholded SVD, where the set of either the left or right singular vectors are represented by low-rank block TT decomposition. Moreover, in order for an efficient computation with sparsely observed data during iteration process, we propose an efficient procedure for computing a multiplication of a sparse matrix with a large matrix in block TT format. In addition, similarly as in [15], we consider that an estimate of the underlying data matrix \( Y \in \mathbb{R}^{I \times J_1 \times J_2 \cdots J_N} \) is represented as a low-rank matrix using block TT format plus a sparse matrix format as follows:

\[ Y \approx \tilde{Y} = X + R_{1\Omega}, \]

where \( R_{1\Omega} \) is the sparse matrix of residuals for the observed data values. By using algebraic operations based on the above format together with the proposed efficient sparse matrix-by-block TT multiplication, the proposed block TT-based method can carry out missing data imputation fast and accurately.

II. BLOCK TENSOR TRAIN (TT) DECOMPOSITION FOR SINGULAR VALUE DECOMPOSITION (SVD) OF LARGE MATRICES

A. Notations

In this work, scalars, vectors, and matrices are denoted by lowercase (a, b, . . .), lowercase bold (a, b, . . .), and uppercase bold letters (A, B, . . .). A tensor is a multi-dimensional array which generalizes vectors and matrices. The size of a tensor can be written as \( I_1 \times I_2 \times \cdots \times I_N \), where \( N \) is called the order of the tensor. Tensors are denoted by uppercase calligraphic letters (\( \mathcal{A}, \mathcal{B}, \ldots \)).

For a tensor \( \mathcal{A} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N} \), its \((i_1, i_2, \ldots, i_N)\)th element is denoted by \( \mathcal{A}_{i_1, i_2, \ldots, i_N} \) or \( \mathcal{A}(i_1, i_2, \ldots, i_N) \).

For a tensor \( \mathcal{A} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N} \) and \( \mathcal{B} \in \mathbb{R}^{J_1 \times \cdots \times J_N} \), their mode-\( k \) unfolding is a matrix \( \mathcal{A}(k)_{i_k, k} = \mathcal{A}_{i_1, i_2, \ldots, i_{k-1}, k, i_{k+1}, \ldots, i_N} \) or \( \mathcal{A}(k)_{i_1, i_2, \ldots, i_{k-1}, i_k, i_{k+1}, \ldots, i_N} \).

The mode-\( (M, 1) \) product of two tensors \( \mathcal{A} \in \mathbb{R}^{I_1 \times \cdots \times I_M} \) and \( \mathcal{B} \in \mathbb{R}^{J_1 \times \cdots \times J_N} \) for all \( i_M = 1, \ldots, I_M \) is defined by

\[
\mathcal{A} \bullet \mathcal{B} \in \mathbb{R}^{I_1 \times \cdots \times I_{M-1} \times J_2 \times \cdots \times J_N}
\]

with entries

\[
(A \bullet B)_{i_1, \ldots, i_{M-1}, j_2, \ldots, j_N} = \sum_{i_M = 1}^{I_M} (A)_{i_1, \ldots, i_M} (B)_{i_M, j_2, \ldots, j_N}.
\]

Moreover, we define the partial products of TT-cores of a block-\( n \) TT decomposition in (2), where \( V_{\neq n} = \mathcal{V}_1 \bullet \cdots \bullet \mathcal{V}_n \in \mathbb{R}^{I_1 \times \cdots \times I_n} \) is called the frame matrix and \( V_n = \mathcal{V}_{n+1} \bullet \cdots \bullet \mathcal{V}_N \in \mathbb{R}^{I_{n+1} \times \cdots \times I_N} \) is the mode-\( n \) unfolding of the \( n \)th TT-core \( \mathcal{V}_n \).

C. SVD Based on Block TT Decomposition

In this section, we describe the proposed SVD algorithm based on block TT decomposition, which will be the most crucial step in the missing data imputation procedure in the next section.

The goal is to compute the \( \mathcal{R}_N \) largest singular values and the corresponding left/right singular vectors of a large matrix \( \mathcal{Y} \in \mathbb{R}^{I_1 \times \cdots \times I_N} \) as

\[
\hat{\mathcal{Y}} \approx \mathcal{U} \mathcal{S} \mathcal{V}^\top,
\]

where \( \mathcal{U} = [u_1, \ldots, u_{\mathcal{R}_N}] \in \mathbb{R}^{I_1 \times \cdots \times I_N} \) is the matrix of the left singular vectors, \( \mathcal{S} = \text{diag}(s_1, \ldots, s_{\mathcal{R}_N}) \) is the diagonal matrix of the \( \mathcal{R}_N \) largest singular values, and \( \mathcal{V} = [v_1, \ldots, v_{\mathcal{R}_N}] \in \mathbb{R}^{I_1 \times \cdots \times I_N} \) is the matrix of the right singular vectors. In this study, we consider that \( \mathcal{V} \) is represented by a block-\( n \) TT decomposition with TT-cores \( \mathcal{V}_1, \ldots, \mathcal{V}_N \) as in (2).

The above problem of computing the largest singular values and the corresponding singular vectors can be expressed as the maximization problem given as

\[
\max_{\mathcal{U}, \mathcal{V}} \quad \text{trace} \left( \mathcal{U}^\top \hat{\mathcal{Y}} \mathcal{V} \right),
\]

subject to \( \mathcal{U}^\top \mathcal{U} = \mathcal{V}^\top \mathcal{V} = \mathcal{I}_{\mathcal{R}_N} \).

Suppose that \( \mathcal{V} \) is in a block-\( n \) TT format (2), i.e., the \( n \)th TT-core is of fourth-order, and all the TT-cores except the \( n \)th one are fixed. Due to the expression in (3), we can reduce the large scale optimization problem in (5) to the smaller scale problem written as

\[
\max_{\mathcal{U}, \mathcal{V}} \quad \text{trace} \left( \mathcal{U}^\top \hat{\mathcal{Y}} \mathcal{V} \right),
\]

subject to \( \mathcal{U}^\top \mathcal{U} = \mathcal{V}^\top \mathcal{V} = \mathcal{I}_{\mathcal{R}_N} \).
The proposed algorithm, bttdSsvdImpute_ALS, iteratively updates $U$, $S$, and the TT-cores $V_1, \ldots, V_N$ of $V$ in (4). One iteration of bttdSsvdImpute_ALS is described in Algorithm 1. It is based on the alternating least squares (ALS) approach which updates $U$ or $V_n$ at each iteration while other components are fixed. Each update is performed by the power method for computing extreme eigenvectors or singular vectors based on the small optimization problem in (6) [17]. After updating $V_n$, the block-$n$ TT format is converted to the block-$(n+1)$ or the block-$(n-1)$ TT format by computing SVD for $V_n$, which helps to keep TT-cores orthogonalized as well.

**Algorithm 1:** One iteration of bttdSsvdImpute_ALS

   end

---

### III. AN ITERATIVE SOFT-THRESHOLDING ALGORITHM FOR MISSING VALUE IMPUTATION

Let $Y \in \mathbb{R}^{I_1 \times J_1 J_2 \cdots J_N}$ denote the original data matrix and $\Omega \subset \{1, \ldots, I\} \times \{1, \ldots, J_1 J_2 \cdots J_N\}$ denote the set of indices of the observed entries, i.e., $(Y)_{i,k}$ is observed if and only if $(i, k) \in \Omega$. We define a projection to the set of observed entries by $P_{\Omega} Y \in \mathbb{R}^{I_1 \times J_1 J_2 \cdots J_N}$ with

$$(P_{\Omega} Y)_{i,k} = \begin{cases} (Y)_{i,k} & \text{if } (i, k) \in \Omega \\ 0 & \text{if } (i, k) \notin \Omega \end{cases} \quad (7)$$

We consider to solve the following nuclear norm regularized minimization problem:

$$\min_X J(X) = \frac{1}{2} \|P_{\Omega} Y - P_{\Omega} X\|^2_F + \lambda \|X\|_*, \quad (8)$$

where $\|A\|_F = \sqrt{\sum_{i,j} a_{i,j}^2}$ is the Frobenius norm of a matrix $A$, and $\|X\|_*$ is called the nuclear norm and is defined by the sum of the singular values of $X$. An algorithm called softImpute has been proposed in [15] and shown to generate estimates which converge to the minimizer of the cost function $J(X)$.

In this paper, we present an extension of the softImpute, which is called bttdSsvdImpute_ALS. The proposed bttdSsvdImpute_ALS generalizes softImpute to higher-order tensor structured data by using block TT decomposition, as described in the previous sections.

The proposed algorithm is described in Algorithm 2. Consider that an estimate of the solution to the problem (8) can be written by $X = \hat{U} \hat{S} \hat{V}^T$, where $V$ is in block-$n$ TT format with TT-cores $\{V_1, \ldots, V_N\}$. The missing values are estimated by the corresponding values of $X$. The estimate of the underlying data matrix $Y$ can be written as

$$\hat{Y} = X + R_\Omega, \quad (9)$$

where $R_\Omega$ is the sparse matrix of residuals defined by

$$R_\Omega = P_{\Omega} Y - P_{\Omega} X.$$ 

The iterations in the proposed algorithm is stopped by the criterion described as follows. At iteration $k = 0, 1, 2, \ldots$, let $X^{(k)} = U^{(k)} S^{(k)} (V^{(k)})^T$ denote the estimated solution to the minimization problem. The iteration is stopped if the rate of changes in the singular vectors is sufficiently small as

$$\text{ratio} = \frac{\|U^{(k-1)} - U^{(k)}\|_F}{\max(\|U^{(k-1)}\|_F, \|U^{(k)}\|_F)} \leq \delta_X, \quad (10)$$

where $\delta_X > 0$ is a predefined tolerance parameter.

### IV. EXPERIMENTS

The experiments were conducted using R software version 3.4.3 on a PC with Intel i5-6200 CPU and a memory of 8 GB running Windows 10 Pro operating system.

#### A. Simulations

Through simulated experiments, we verify convergence of the block TT-based proposed method and compare performances of the proposed method with the matrix-based standard method. Details about the simulated data are described in each subsection.
The tolerance parameter for stopping criterion was set by $\delta_X = 10^{-6}$. Fig. 1 shows the convergence of the cost function of the solution matrix estimated by the proposed method. We can see that with the rank $R_X = 1$, the convergence speed is relatively slow compared to the other cases of $R_X = 2, 3, 4, 5$. This is because the rank $R_X$ larger than 1 allows TT-ranks to adaptively change during iteration process, while the rank $R_X = 1$ does not. Note that the TT-ranks were initialized by $R_n = 1$ for all $n$, which means that, even if the TT-ranks did not change at $R_n = 1$ for the case of $R_X = 1$, the sparsely observed values was estimated accurately with $\delta_X = 10^{-6}$. This is a reasonable result because there exists a rank-1 matrix which perfectly fit with the observed values $Y = [y_{1,1}, \ldots, y_{J,J}]^T$, e.g., $X = [y, y, \ldots, y] = y_1^T$, where $1$ is a vector of ones, and the vector $1$ has the TT-ranks $R_n = 1$ for all $n$.

#### 2) Low-rank Matrices: In this section, low-rank data matrices $Y$ were randomly generated by using block TT decomposition as

$$ Y = U_0S_0V_0^T, $$

where $U_0 \in \mathbb{R}^{I \times R_X}$ were generated from standard normal distribution and then orthogonalized, $S_0 = \text{diag}(s_1, \ldots, s_{R_Y}) \in \mathbb{R}^{R_Y \times R_Y}$ were generated from uniform $\{0, 1\}$ distribution, and TT-cores of block-1 TT tensor $V_0 \approx Y_1 \cdots \cdot Y_N \in \mathbb{R}^{I \times R_Y}$ were randomly generated by standard normal distribution and then left-orthogonalized. The TT-ranks of $V_0$ were set at $R_n = 2$, and other parameters were set at $N \in \{2, 3\}$, $I = 100$, $J_n \in \{4, 8, 12, 16, 20\}$, $R_Y = R_X = 4$, $\delta_X = 0.0005$, $\lambda = 0$. The observed values were randomly sampled, and the number of observed values, $|\Omega|$, were set at

$$ |\Omega| = \rho I J_1 \cdots J_N. $$

The proportion was set by $\rho \in \{0.2, 0.4\}$ to simulate sparsely observed data matrices. The simulation can be conducted for other values of $\rho$ in future works.

We compared performances of the block TT-based proposed method with the matrix-based method. In the matrix-based
method, the right singular vectors $V$ are estimated in full matrix format. In the case that $N = 1$, the block TT-based method and the matrix-based method are identical. As a performance measure, the relative root mean squared error (RRMSE) was calculated by

$$ RRMSE = \frac{\|X - Y\|_F}{\|Y\|_F}.$$ 

The simulation results for $N = 2$ are illustrated in Tables I and II. Each value in the tables show the difference of the RRMSE values of the block TT-based method and the matrix-based method, i.e.,

$$RRMSE(\text{blockTT}) - RRMSE(\text{matrix}).$$

The negative value implies that the block TT-based method achieved higher accuracy in the missing data imputation. In Tables I and II, we can see that the higher the size $J_n$, the block TT-based method achieved higher accuracy.

The simulation results for $N = 3$ are illustrated in Tables III and IV. We did not run the simulation for large proportion $\rho \geq 0.5$ and large size $J_n \geq 16$ because the number of observed data values increased largely so that computational costs became relatively huge. In the tables, we can see that the proposed block TT-based method was more accurate for relatively large sizes $J_n$. Moreover, compared to the case of lower order $N = 2$, the proposed block TT-based method achieved higher accuracy for the case of higher order $N = 3$, which implies higher efficiency for higher order tensor structured data. In addition, it is remarkable that even for the cases of high order, large data sizes, and large proportion of missing data (e.g., $\rho \leq 0.2$), the low-rank block TT-based method could recover missing data successfully.

### V. Conclusions and Discussion

In this work, we proposed a novel method for missing data imputation based on block TT decomposition. Since the block TT decomposition computes SVD of large matrices approximately, the proposed method successfully extended the existing method on low-rank matrix data to low-rank tensor structured data, while potentially inheriting favorable properties such as global convergence. Compared to the matrix-based method, the proposed method could achieve higher accuracy in the cases of higher order ($N > 1$) tensor structured data in the simulated experiments.

On the other hand, [1] and [13] have proposed SVD algorithms for large scale matrices based on TT decompositions. However, existing SVD methods based on TT decompositions assume that the large scale matrices are in the TT matrix format, whereas in this work the large scale matrices are in the low-rank matrix plus sparse format. There are several challenges for missing data imputation based on (block) TT decompositions, (i) Alternating least squares (ALS)-based algorithms often show slow convergence speed, especially for high dimensional data problems. Modified ALS algorithm can be an alternative, but its computational cost is usually higher than that of ALS algorithms [13]. (ii) The computational cost highly depends on the number of observed data values, which requires more efficient way of computing sparse matrix-by-tensor multiplication. In this sense, recently arising new trends such as randomized methods [1] can be a new direction.
